This manual covers the following areas:

- [Get started](#) — An overview of the official Neo4j Go Driver and how to connect to a Neo4j database.
- [Client applications](#) — How to manage database connections within an application.
- [Cypher workflow](#) — How to create units of work and provide a logical context for that work.
- [The session API](#) — How the types and values used by Cypher map to native language types.
- [Driver terminology](#) — Terminology for drivers.

Who should read this?

This manual is written for Go developers building a Neo4j client application.

Learn with GraphAcademy

Building Neo4j Applications with Go

In this free course, follow a walk through the steps to integrate Neo4j into your Go projects. You will learn about the Neo4j Go Driver, how sessions and transactions work and how to query Neo4j from an existing application.

[Learn more](#)

Get started

About the official Go driver

Neo4j provides official drivers for a number of popular programming languages. These drivers are supported by Neo4j.

Community drivers also exist for many languages, but vary greatly in terms of feature sets, maturity, and support. To find more about community drivers, visit <https://neo4j.com/developer/language-guides/>.

The following languages and frameworks are officially supported by Neo4j:

Table 1. Supported languages and frameworks for the 5.x driver series

Language/framework	Versions supported
.NET	.NET Standard 2.0
Go	All officially maintained Go versions .
Java	Java 17.
JavaScript	All LTS versions of Node.JS , specifically the 4.x and 6.x series runtimes.
Python	Python 3.7 and above.

The driver API is intended to be topologically agnostic. This means that the underlying database topology — single instance, Causal Cluster, etc. — can be altered without requiring a corresponding alteration to application code.

In the general case, only the [connection URI](#) needs to be modified when changes are made to the topology.

The official drivers do not support HTTP communication. If you need an HTTP driver, choose one of the community drivers.

See also the [HTTP API documentation](#).

Driver versions and installation

Wherever possible, it is recommended to use the latest stable driver release available. This will provide the greatest degree of stability and will ensure that the full set of server functionality is available. The drivers, when used with Neo4j Enterprise Edition, come with full cluster routing support. The drivers make no explicit distinction between Enterprise Edition and Community Edition however, and simply operate with the functionality made available by Neo4j itself.

Example 1. Acquire the driver

To find the latest version of the driver, visit <https://github.com/neo4j/neo4j-go-driver/releases>.

To install the latest version of the driver using `go get`:

```
go get github.com/neo4j/neo4j-go-driver/v4
```

The release notes for this driver are available [here](#).

A "Hello World" example

The example below shows the minimal configuration necessary to interact with Neo4j through the Go driver.

Example 2. Hello World

```
Unresolved directive in get-started.adoc - include::opt/teamcity-agent/work/617a3392e5115979/neo-technology/mma/go-manual/build/5/mono/modules/api/neo4j/test-integration/examples_test.go[tags=hello-world]
```

Driver API docs

For a comprehensive listing of all driver functionality, please see the [Go API reference documentation](#).

Client applications

This section describes how to manage database connections within an application.

The Driver Object

Neo4j client applications require a *Driver Object* which, from a data access perspective, forms the backbone of the application. It is through this object that all Neo4j interaction is carried out, and it should therefore be made available to all parts of the application that require data access.

In languages where [thread safety](#) is an issue, the Driver Object can be considered **thread-safe**.

A note on lifecycle

Applications will typically construct a Driver Object on startup and destroy it on exit.

Destroying a Driver Object will immediately shut down any connections previously opened via that Driver Object, by closing the associated connection pool.

This will have the consequence of rolling back any open transactions, and closing any unconsumed results.

To construct a driver instance, a [connection URI](#) and [authentication information](#) must be supplied.

Additional configuration details can be supplied if required. The configuration details are immutable for the lifetime of the Driver Object. Therefore, if multiple configurations are required (such as when working with multiple database users) then multiple Driver Objects must be used.

Example 3. The driver lifecycle

```
Unresolved directive in client-applications.adoc - include:::/opt/teamcity-agent/work/617
a3392e5115979/neo-technology/mma/go-manual/build/5/mono/modules/api/neo4j/test-integration
/examples_test.go[tags=driver-lifecycle]
```

Connection URIs

A connection URI identifies a graph database and how to connect to it.

The **encryption** and **trust** settings provide detail to how that connection should be secured.

Starting with Neo4j 4.0, client-server communication uses only **unencrypted local connections by default**. This is a change from previous versions, which switched on encryption by default, but generated a self-signed certificate out of the box.

When a full certificate is installed, and encryption is enabled on the driver, full certificate checks are carried out (refer to [Operations Manual → SSL framework](#)). Full certificates provide better overall security than self-signed certificates as they include a complete chain of trust back to a root certificate authority.

Neo4j Aura is a *secure hosted service* backed by full certificates signed by a root certificate authority.

To connect to **Neo4j Aura**, driver users must *enable encryption* and the complete set of certificate checks (the latter of which are enabled by default).

For more information, see [Examples](#) below.

Initial address resolution

The address provided in a `neo4j://` URI is used for initial and fallback communication only.

This communication occurs to *bootstrap the routing table*, through which all subsequent communication is carried out. Fallback occurs when the driver is unable to contact any of the addresses held in the routing table. The initial address is once again reused to bootstrap the system.

Several options are available for providing this initial logical-to-physical host resolution. These include *regular DNS*, *custom middleware* such as a load balancer, and the Driver Object *resolver function*, all of which are described in the following sections.

DNS resolution

DNS resolution is the default, and always-available option. As it is possible to configure DNS to resolve a single host name down to multiple IP addresses, this can be used to expose all core server IP addresses under a single host name.

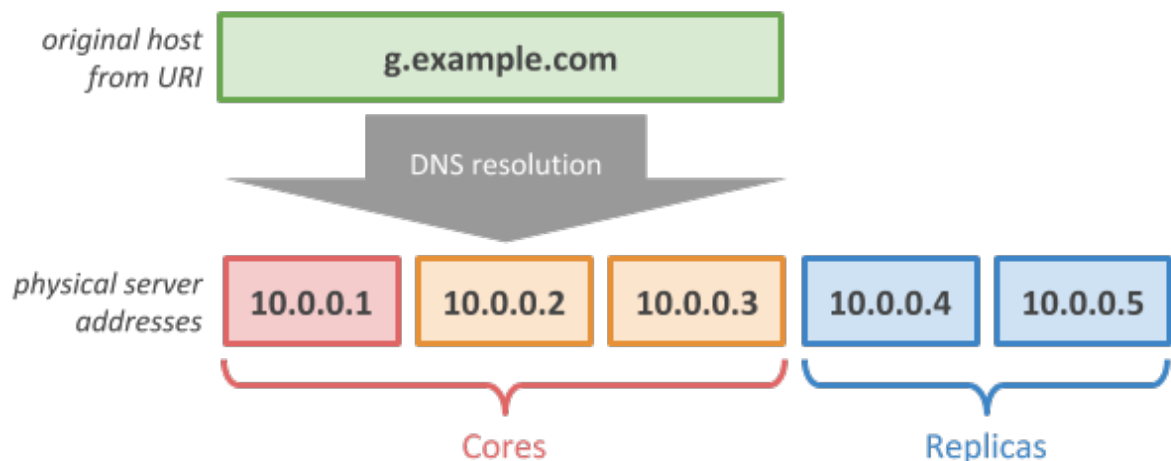

Figure 1. Initial address resolution over DNS

Custom middleware

Middleware, such as a load balancer, can be used to group the core servers under a single public address.

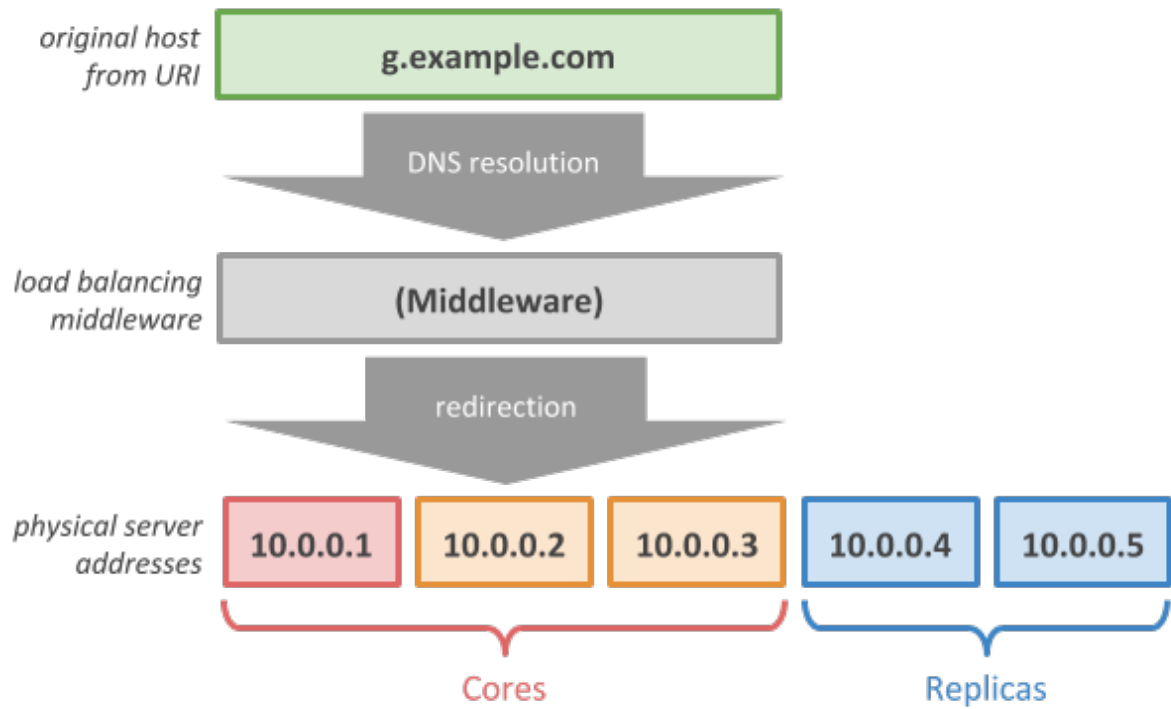

Figure 2. Initial address resolution using custom middleware

Resolver function

Neo4j Drivers also present an address resolution intercept hook called the *resolver function*.

This takes the form of a callback function that accepts a single input address and returns multiple output addresses. The function may hard code the output addresses or may draw them from another configuration source, as required.

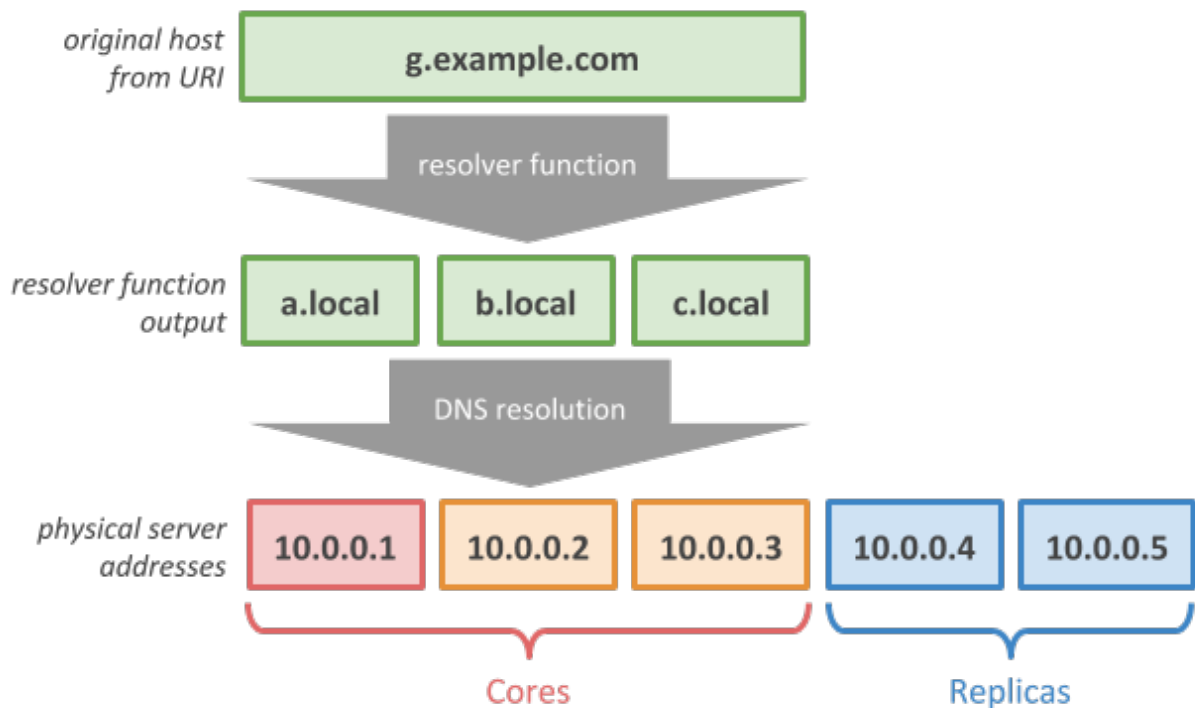

Figure 3. Initial address resolution using resolver function

The example below shows how to expand a single address into multiple (hard-coded) output addresses:

Example 4. Custom Address Resolver

```
Unresolved directive in client-applications.adoc - include::opt/teamcity-agent/work/617
a3392e5115979/neo-technology/mma/go-manual/build/5/mono/modules/api/neo4j/test-integration
/examples_test.go[tags=config-custom-resolver]
```

Routing table

The routing table acts like the glue between the driver connectivity layer and the database surface. This table contains a list of server addresses, grouped as *readers* and *writers*, and is refreshed automatically by the driver as required.

The driver does not expose any API to work directly with the routing table, but it can sometimes be useful to explore when troubleshooting a system.

Routing context

A routing context can be included as the query part of a `neo4j://` URI.

Routing contexts are defined by means of *server policies* and allow customization of the contents of the routing table.

Example 5. Configure a routing driver with routing context

This example will assume that Neo4j has been configured for server policies as described in [Neo4j Operations Manual → Load balancing for multi-data center systems](#). In particular, a server policy called `europa` has been defined. Additionally, we have a server `neo01.graph.example.com` to which we wish to direct the driver.

This URI will use the server policy `europa`:

```
neo4j://neo01.graph.example.com?policy=europa
```

Server-side configuration to enable routing drivers with routing context

A prerequisite for using a routing driver with routing context is that the Neo4j database is operated on a [Multi-data center licensing option](#) enabled. Additionally, the routing contexts must be defined within the cluster as *routing policies*.

For details on how to configure *multi-data center routing policies* for a Causal Cluster, please refer to [Operations Manual → Causal Clustering](#).

Exposing a single instance deployment on a remote host using the `neo4j` URI scheme

If you are using a *single instance* of Neo4j, deployed on a remote machine whilst using the `neo4j` URI scheme, you will need to complete additional configuration of the server.

To make the server aware of its deployment environment, you need to configure `default_advertised_address` with your deployment machine's host name, as visible from the client machine.

Examples

Connection URIs are typically formed according to the following pattern:

```
neo4j://<HOST>:<PORT>[?<ROUTING_CONTEXT>]
```

This targets a routed Neo4j service that may be fulfilled by either a cluster or a single instance. The `HOST` and `PORT` values contain a logical hostname and port number targeting the entry point to the Neo4j service (e.g. `neo4j://graph.example.com:7687`).

In a clustered environment, the URI address will resolve to one of more of the core members; for standalone installations, this will simply point to that server address. The `ROUTING_CONTEXT` option allows for customization of the routing table and is discussed in more detail in [Routing context](#).

An alternative URI form, using the `bolt` URI scheme (e.g. `bolt://graph.example.com:7687`), can be used when a *single point-to-point connection is required*. This variant is useful for the subset client applications (such as admin tooling) that need to be aware of individual servers, as opposed to those which require a highly available database service.

```
bolt://<HOST>:<PORT>
```

Each of the `neo4j` and `bolt` URI schemes permit variants that contain extra encryption and trust information. The `+s` variants enable encryption with a full certificate check, and the `+ssc` variants enable encryption, but with no certificate check. This latter variant is designed specifically for use with self-signed certificates.

Table 2. Available URI schemes

URI scheme	Routing	Description
<code>neo4j</code>	Yes	Unsecured
<code>neo4j+s</code>	Yes	Secured with full certificate
<code>neo4j+ssc</code>	Yes	Secured with self-signed certificate
<code>bolt</code>	No	Unsecured

URI scheme	Routing	Description
<code>bolt+s</code>	No	Secured with full certificate
<code>bolt+ssc</code>	No	Secured with self-signed certificate

Neo4j 3.x did not provide a routing table in single instance mode and therefore you should use a `bolt://` URI if targeting an older, non-clustered server.

The table below provides example code snippets for different deployment configurations. Each snippet expects an `auth` variable to have been previously defined, containing the authentication details for that connection.

Connecting to a service

The tables below illustrate examples of how to connect to a service with routing:

Table 3. Neo4j Aura or Neo4j >= 4.x, secured with full certificate

Product	Neo4j Aura, Neo4j >= 4.x
Security	Secured with full certificate
Code snippet	<pre>neo4j.NewDriver("neo4j+s://graph.example.com:7687", auth)</pre>
Comments	This is the default (and only option) for Neo4j Aura.

Table 4. Neo4j >= 4.x, unsecured

Product	Neo4j >= 4.x
Security	Unsecured
Code snippet	<pre>neo4j.NewDriver("neo4j://graph.example.com:7687", auth);</pre>
Comments	This is the default for Neo4j >= 4.x series

Table 5. Neo4j >= 4.x, secured with self-signed certificate

Product	Neo4j >= 4.x
Security	Secured with self-signed certificate

Code snippet

```
neo4j.NewDriver("neo4j+ssc://graph.example.com:7687", auth)
```

To connect to a service without routing, you can replace `neo4j` with `bolt`.

Authentication

Authentication details are provided as an auth token which contains the user names, passwords or other credentials required to access the database. Neo4j supports multiple authentication standards but uses **basic authentication** by default.

Basic authentication

The basic authentication scheme is backed by a password file stored within the server and requires applications to provide a user name and password. For this, use the basic auth helper:

Example 6. Basic authentication

```
Unresolved directive in client-applications.adoc - include::/opt/teamcity-agent/work/617  
a3392e5115979/neo-technology/mma/go-manual/build/5/mono/modules/api/neo4j/test-integration  
/examples_test.go[tags=basic-auth]
```

The basic authentication scheme can also be used to authenticate against an LDAP server.

Kerberos authentication

The Kerberos authentication scheme provides a simple way to create a Kerberos authentication token with a base64 encoded server authentication ticket. The best way to create a Kerberos authentication token is shown below:

Example 7. Import Kerberos authentication

```
Unresolved directive in client-applications.adoc - include::/opt/teamcity-agent/work/617  
a3392e5115979/neo-technology/mma/go-manual/build/5/mono/modules/api/neo4j/test-integration  
/examples_test.go[tags=kerberos-auth]
```

The Kerberos authentication token can only be understood by the server if the server has the [Kerberos Add-on](#) installed.

Custom authentication

For advanced deployments, where a custom security provider has been built, the custom authentication helper can be used.

Example 8. Custom authentication

```
Unresolved directive in client-applications.adoc - include::/opt/teamcity-agent/work/617a3392e5115979/neo-technology/mma/go-manual/build/5/mono/modules/api/neo4j/test-integration/examples_test.go[tags=custom-auth]
```

Configuration

ConnectionAcquisitionTimeout

The maximum amount of time a session will wait when requesting a connection from the connection pool. For connection pools where all connections are currently being used and the `MaxConnectionPoolSize` limit has been reached, a session will wait this duration for a connection to be made available. Since the process of acquiring a connection may involve creating a new connection, **ensure that the value of this configuration is higher than the configured `ConnectionTimeout`.**

Setting a low value will allow for transactions to **fail fast** when all connections in the pool have been acquired by other transactions. Setting a higher value will result in these transactions being queued, increasing the chances of eventually acquiring a connection at the cost of longer time to receive feedback on failure. Finding an optimal value may require an element of experimentation, taking into consideration the expected levels of parallelism within your application as well as the `MaxConnectionPoolSize`.

Default: 60 seconds

Example 9. Configure connection pool

```
Unresolved directive in client-applications.adoc - include::/opt/teamcity-agent/work/617a3392e5115979/neo-technology/mma/go-manual/build/5/mono/modules/api/neo4j/test-integration/examples_test.go[tags=config-connection-pool]
```

ConnectionTimeout

The maximum amount of time to wait for a TCP connection to be established. Connections are only created when a session requires one unless there is an available connection in the connection pool. The driver maintains a pool of open connections which can be loaned to a session when one is available. If a connection is not available, then an attempt to create a new connection (provided the `MaxConnectionPoolSize` limit has not been reached) is made with this configuration option, providing the maximum amount of time to wait for the connection to be established.

In environments with high latency and high occurrences of connection timeouts it is recommended to configure a higher value. For lower latency environments and quicker feedback on potential network issues configure with a lower value.

Default: 30 seconds

Example 10. Configure connection timeout

```
Unresolved directive in client-applications.adoc - include::/opt/teamcity-agent/work/617a3392e5115979/neo-technology/mma/go-manual/build/5/mono/modules/api/neo4j/test-integration/examples_test.go[tags=config-connection-timeout]
```

CustomResolver

Specify a custom server address resolver used by the routing driver to resolve the initial address used to create the driver. See [Resolver function](#) for more details.

MaxConnectionLifetime

The maximum duration the driver will keep a connection for before being removed from the pool. Note that while the driver will respect this value, it is possible that the network environment will close connections inside this lifetime. This is beyond the control of the driver. The check on the connection's lifetime happens when a session requires a connection. If the available connection's lifetime is over this limit it is closed and a new connection is created, added to the pool and returned to the requesting session. Changing this configuration value would be useful in environments where users don't have full control over the network environment and wish to proactively ensure all connections are ready.

Setting this option to a low value will cause a high connection churn rate, and can result in a performance drop. It is recommended to pick a value smaller than the maximum lifetime exposed by the surrounding system infrastructure (such as operating system, router, load balancer, proxy and firewall). Negative values result in lifetime not being checked.

Default: 1 hour (3600 seconds)

MaxConnectionPoolSize

The maximum total number of connections allowed, per host (i.e. cluster nodes), to be managed by the connection pool. In other words, for a direct driver using the `bolt://` scheme, this sets the maximum number of connections towards a single database server. For a driver connected to a cluster using the `neo4j://` scheme, this sets the maximum amount of connections per cluster member. If a session or transaction tries to acquire a connection at a time when the pool size is at its full capacity, it must wait until a free connection is available in the pool or the request to acquire a new connection times out. The connection acquiring timeout is configured via [ConnectionAcquisitionTimeout](#).

This configuration option allows you to manage the memory and I/O resources being used by the driver and tuning this option is dependent on these factors, in addition to number of cluster members.

Default: 100 connections

MaxTransactionRetryTime

The maximum amount of time that a managed transaction will retry for before failing. Queries that are executed within a managed transaction gain the benefit of being retried when a transient error occurs. When this happens the transaction is retired multiple times up to the [MaxTransactionRetryTime](#).

Configure this option higher in high latency environments or if you are executing many large transactions which could limit the number of times that they are retired and therefore their chance to succeed. Configure lower in low latency environments and where your workload mainly consists of

many smaller transactions. Failing transactions faster may highlight the reasons behind the transient errors making it easier to fix underlying issues.

Default: 30 seconds

Example 11. Configure maximum retry time

```
Unresolved directive in client-applications.adoc - include::/opt/teamcity-agent/work/  
617a3392e5115979/neo-technology/mma/go-manual/build/5/mono/modules/api/neo4j/test-integration  
/examples_test.go[tags=config-max-retry-time]
```

TrustStrategy

This is not applicable for the Go driver, as it uses a URI to determine trust strategy. RootCAs can be used to configure custom CAs.

Logging

All official Neo4j Drivers log information to standard logging channels. This can typically be accessed in an ecosystem-specific way.

The code snippet below demonstrates how to redirect log messages to standard output:

```
driver, err := neo4j.NewDriver(..., func(c *neo4j.Config) { c.Log = neo4j.ConsoleLogger(neo4j.DEBUG) })
```

Cypher workflow

This section describes how to create units of work and provide a logical context for that work.

Overview

The Neo4j Drivers expose a Cypher Channel over which database work can be carried out (see the [Cypher Manual](#) for more information on the Cypher Query Language).

Work itself is organized into *sessions*, *transactions* and *queries*, as follows:

Figure 4. Sessions, queries and transactions

Sessions are always bound to a **single transaction context**, which is typically an individual database.

Using the bookmark mechanism, sessions also provide a guarantee of correct transaction sequencing, even when transactions occur over multiple cluster members. This effect is known as **causal chaining**.

Sessions

Sessions are **lightweight containers for causally chained sequences of transactions** (see [Operations Manual](#) → [Causal consistency](#)). They essentially provide context for storing transaction sequencing information in the form of bookmarks.

When a transaction begins, the session in which it is contained acquires a connection from the driver connection pool. On commit (or rollback) of the transaction, the session releases that connection again. This means that it is only when a session is carrying out work that it occupies a connection resource. When idle, no such resource is in use.

Due to the sequencing guaranteed by a session, sessions may only host **one transaction at a time**. For parallel execution, multiple sessions should be used. In languages where **thread safety** is an issue, **sessions should not be considered thread-safe**.

Closing a session forces any open transaction to be rolled back, and its associated connection to consequently be released back into the pool.

Sessions are bound to a single transactional context, specified on construction. Neo4j exposes each database inside its own context, thereby prohibiting cross-database transactions (or sessions) by design. Similarly, *sessions bound to different databases may not be causally chained by propagating bookmarks between them.*

Individual language drivers provide several session classes, each oriented around a particular programming style. Each session class provides a similar set of functionality but offers client applications a choice based on how the application is structured and what frameworks are in use, if any.

The session classes are described in [The session API](#). For more details, please see the [API documentation](#).

Transactions

Transactions are **atomic units of work** containing one or more **Cypher Queries**. Transactions may contain read or write work, and will generally be routed to an appropriate server for execution, where they will be carried out in their entirety. In case of a transaction failure, the transaction needs to be retried from the beginning. This is the responsibility of the [transaction manager](#).

The Neo4j Drivers provide **transaction management** via the [transaction function](#) mechanism. This mechanism is exposed through methods on the Session object which accept a function object that can be played multiple times against different servers until it either succeeds or a timeout is reached. This approach is recommended for most client applications.

A convenient **short-form alternative** is the [auto-commit](#) transaction mechanism. This provides a limited form of transaction management for single-query transactions, as a trade-off for a slightly smaller code overhead. This form of transaction is useful for **quick scripts and environments where high availability guarantees are not required**. It is also the required form of transaction for running [Cypher Manual](#) → **CALL {} IN TRANSACTIONS** queries, which are the only type of Cypher Query to manage their own transactions.

A lower-level **unmanaged transaction API** is also available for advanced use cases. This is useful when an alternative transaction management layer is applied by the client, in which error handling and retries need to be managed in a custom way.

To learn more about how to use unmanaged transactions, see [API documentation](#) for the relevant language.

Queries and results

Queries consist of a request to the server to execute a Cypher statement, followed by a response back to the client with the result. Results are transmitted as a **stream of records**, along with header and footer metadata, and can be incrementally consumed by a client application. With reactive capabilities, the semantics of the record stream can be enhanced by allowing a Cypher result to be paused or cancelled part-way through.

To execute a Cypher Query, the **query text** is required along with an optional set of **named parameters**. The text can contain **parameter placeholders** that are substituted with the corresponding values at

runtime. While it is possible to run non-parameterized Cypher Queries, **good programming practice is to use parameters in Cypher Queries whenever possible**. This allows for the caching of queries within the Cypher Engine, which is beneficial for performance. Parameter values should adhere to [Cypher values](#).

A result summary is also generally available. This contains additional information relating to the query execution and the result content. For an **EXPLAIN** or **PROFILE** query, this is where the query plan is returned. See [Cypher Manual → Profiling a query](#) for more information on these queries.

Causal chaining and bookmarks

When working with a **Causal Cluster**, transactions can be chained, via a session, to ensure **causal consistency**. This means that for any two transactions, it is guaranteed that the second transaction will begin only after the first has been successfully committed. This is true even if the transactions are carried out on different physical cluster members. For more information on Causal Clusters, please refer to [Operations Manual → Clustering](#).

Internally, causal chaining is carried out by passing bookmarks between transactions. Each bookmark records one or more points in transactional history for a particular database, and can be used to inform cluster members to carry out units of work in a particular sequence. On receipt of a bookmark, the server will block until it has caught up with the relevant transactional point in time.

An initial bookmark is sent from client to server on beginning a new transaction, and a final bookmark is returned on successful completion. Note that this applies to both read and write transactions.

Bookmark propagation is carried out automatically within sessions and does not require any explicit signal or setting from the application. To opt out of this mechanism, for unrelated units of work, applications can use multiple sessions. This avoids the small latency overhead of the causal chain.

Bookmarks can be passed between sessions by extracting the last bookmark from a session and passing this into the construction of another. Multiple bookmarks can also be combined if a transaction has more than one logical predecessor. Note that it is only when chaining across sessions that an application will need to work with bookmarks directly.

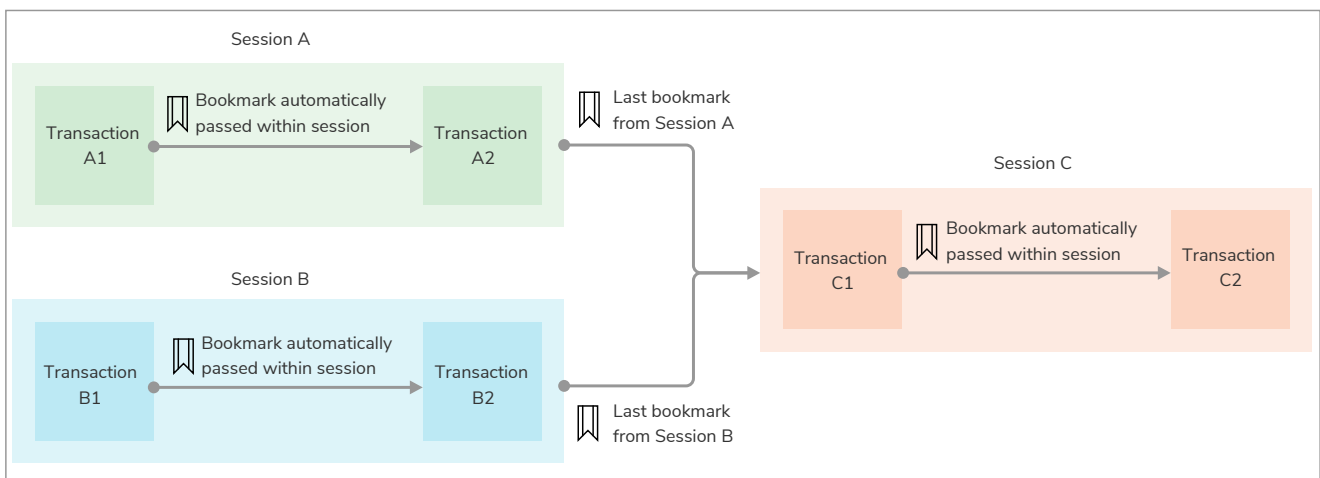

Figure 5. Passing bookmarks

Example 12. Pass bookmarks

```
Unresolved directive in cypher-workflow.adoc - include::/opt/teamcity-agent/work/617a3392e5115979/neo-technology/mma/go-manual/build/5/mono/modules/api/neo4j/test-integration/examples_test.go[tags=pass-bookmarks]
```

Routing transactions using access modes

Transactions can be executed in either *read* or *write* mode; this is known as the **access mode**. In a Causal Cluster, each transaction will be routed to an appropriate server based on the mode. When using a single instance, all transactions will be passed to that one server.

Routing Cypher by identifying reads and writes can improve the utilization of available cluster resources. Since read servers are typically more plentiful than write servers, it is beneficial to direct read traffic to read servers instead of the write server. Doing so helps in keeping write servers available for write transactions.

Access mode is generally specified by the method used to call the transaction function. Session classes provide a method for calling reads and another for writes.

As a fallback for *auto-commit* and *unmanaged transactions*, a **default access mode** can also be provided at *session level*. This is only used in cases when the access mode cannot otherwise be specified. *In case a transaction function is used within that session, the default access mode will be overridden.*

The driver does not parse Cypher and therefore cannot automatically determine whether a transaction is intended to carry out read or write operations. As a result, a write transaction tagged as a read will still be sent to a read server, but will fail on execution.

Example 13. Read-write transaction

```
Unresolved directive in cypher-workflow.adoc - include::/opt/teamcity-agent/work/617a3392e5115979/neo-technology/mma/go-manual/build/5/mono/modules/api/neo4j/test-integration/examples_test.go[tags=read-write-transaction]
```

Databases and execution context

Database selection

You pass the name of the database to the driver during session creation. If you don't specify a name, the default database is used. The database name must not be `null`, nor an empty string.

The selection of database is only possible when the driver is connected against Neo4j Enterprise Edition. Changing to any other database than the default database in Neo4j Community Edition will lead to a runtime error.

The following example illustrates the concept of DBMS [Cypher Manual](#) → [Transactions](#) and shows how queries to multiple databases can be issued in one driver transaction. It is annotated with comments

describing how each operation impacts database transactions.

```
var session = driver.session(SessionConfig.forDatabase( "foo" ))
// a DBMS-level transaction is started
var transaction = session.begin()

// a transaction on database "foo" is started automatically with the first query targeting foo
transaction.run("MATCH (n) RETURN n").list()

// a transaction on database "bar" is started
transaction.run("USE bar MATCH (n) RETURN n").list()

// executes in the transaction on database "foo"
transaction.run("RETURN 1").consume()

// executes in the transaction on database "bar"
transaction.run("USE bar RETURN 1").consume()

// commits the DBMS-level transaction which commits the transactions on databases "foo" and
// "bar"
transaction.commit()
```

Please note that the database that is requested must exist.

Example 14. Database selection on session creation

```
Unresolved directive in cypher-workflow.adoc - include::/opt/teamcity-agent/work/617a3392e5115979/neo
-technology/mma/go-manual/build/5/mono/modules/api/neo4j/test-integration/examples_test.go[tags
=database-selection]
```

Type mapping

Drivers translate between *application language types* and the *Cypher Types*.

To pass parameters and process results, it is important to know the basics of how Cypher works with types and to understand how the Cypher Types are mapped in the driver.

The table below shows the available data types. All types can be potentially found in the result, although not all types can be used as parameters.

Cypher Type	Parameter	Result
<code>null*</code>	✓	✓
<code>List</code>	✓	✓
<code>Map</code>	✓	✓
<code>Boolean</code>	✓	✓
<code>Integer</code>	✓	✓
<code>Float</code>	✓	✓
<code>String</code>	✓	✓
<code>ByteArray</code>	✓	✓
<code>Date</code>	✓	✓
<code>Time</code>	✓	✓
<code>LocalTime</code>	✓	✓
<code>DateTime</code>	✓	✓
<code>LocalDateTime</code>	✓	✓
<code>Duration</code>	✓	✓
<code>Point</code>	✓	✓
<code>Node**</code>		✓
<code>Relationship**</code>		✓
<code>Path**</code>		✓

* The null marker is not a type but a placeholder for absence of value. For information on how to work with null in Cypher, please refer to [Cypher Manual → Working with null](#).

** Nodes, relationships and paths are passed in results as snapshots of the original graph entities. While the original entity IDs are included in these snapshots, no permanent link is retained back to the underlying server-side entities, which may be deleted or otherwise altered independently of the client copies. Graph structures may not be used as parameters because it depends on application context whether such a parameter would be passed by reference or by value, and Cypher provides no mechanism to denote this. Equivalent functionality is available by simply passing either the ID for pass-by-reference, or an extracted map of properties for pass-by-value.

The Neo4j Drivers map Cypher Types to and from native language types as depicted in the table below. Custom types (those not available in the language or standard library) are highlighted in bold.

Table 6. Map Neo4j types to Go types

Neo4j type	Go type
<code>null</code>	<code>nil</code>
<code>List</code>	<code>[]interface{}</code>

Neo4j type	Go type
Map	<code>map[string]interface{}</code>
Boolean	<code>bool</code>
Integer	<code>int64</code>
Float	<code>float64</code>
String	<code>string</code>
ByteArray	<code>[]byte</code>
Date	<code>neo4j.Date</code>
Time	<code>neo4j.OffsetTime</code>
LocalTime	<code>neo4j.LocalTime</code>
DateTime	<code>time.Time*</code>
LocalDateTime	<code>neo4j.LocalDateTime</code>
Duration	<code>neo4j.Duration</code>
Point	<code>neo4j.Point</code>
Node	<code>neo4j.Node</code>
Relationship	<code>neo4j.Relationship</code>
Path	<code>neo4j.Path</code>

* When a `time.Time` value is sent/received through the driver and its `Zone()` returns a name of `Offset`, the value is stored with its offset value rather than its zone name.

Geospatial Types

This section lists some basic usage of the geospatial types provided by the Go Driver.

Point2D

Represents a two-dimensional in Cartesian space or in the WGS84 space. The field `SpatialRefId` indicates the type of the coordinate.

The following table lists the possible values for `SpatialRefId`:

SpatialRefId	Description
7203	2D point in the cartesian space.
4326	2D point in the WGS84 space.

Examples of two-dimensions points instantiation and reading:

```
Unresolved directive in cypher-workflow.adoc - include::/opt/teamcity-agent/work/617a3392e5115979/neo-technology/mma/go-manual/build/5/mono/modules/api/neo4j/test-integration/examples_test.go[tags=geospatial-types-point2d]
```

Point3D

Represents a three-dimensional point in Cartesian space or in the WGS84 space. The field `SpatialRefId` indicates the type of the coordinate.

The following table lists the possible values for `SpatialRefId`:

SpatialRefId	Description
9157	3D point in the cartesian space.
4979	3D point in the WGS84 space.

Examples of three-dimensions points instantiation and reading:

```
Unresolved directive in cypher-workflow.adoc - include::/opt/teamcity-agent/work/617a3392e5115979/neo-technology/mma/go-manual/build/5/mono/modules/api/neo4j/test-integration/examples_test.go[tags=geospatial-types-point2d]
```

Exceptions and error handling

When executing Cypher or carrying out other operations with the driver, certain exceptions and error cases may arise. *Server-generated exceptions* are each associated with a `status code` that describes the nature of the problem and a message that provides more detail.

The classifications are listed in the table below.

Table 7. Server status code classifications

Classification	Description
ClientError	The client application has caused an error. The application should amend and retry the operation.
DatabaseError	The server has caused an error. Retrying the operation will generally be unsuccessful.
TransientError	A temporary error has occurred. The application should retry the operation.

Service unavailable

A **Service Unavailable** exception will be signalled when the driver is no longer able to establish communication with the server, even after retries.

Encountering this condition usually indicates a fundamental networking or database problem.

While certain mitigations can be made by the driver to avoid this issue, there will always be cases when this is impossible. As such, it is highly recommended to ensure client applications contain a code path that can be followed when the client is no longer able to communicate with the server.

Transient errors

Transient errors are those which are generated by the server and marked as safe to retry without alteration to the original request. Examples of such errors are deadlocks and memory issues.

When using transaction functions, the driver will usually be able to automatically retry when a transient failure occurs. The function `IsRetryable` gives insights into whether a further attempt might be successful.

The session API

This section details the Session API that is made available by the driver.

Sessions provide a "classic" **blocking style** API for Cypher execution. In general, sessions provide the easiest programming style to work with since API calls are executed in a strictly sequential fashion.

Lifecycle

The session lifetime extends from session construction to session closure. In languages that support them, simple sessions are usually scoped within a context block; this ensures that they are properly closed and that any underlying connections are released and not leaked.

```
session := driver.NewSession(...)
defer session.Close()
// transactions go here
```

Sessions can be configured in a number of different ways. This is carried out by supplying configuration inside the session constructor. See [Session configuration](#) for more details.

Transaction functions

Transaction functions are used for containing transactional units of work. This form of transaction requires minimal boilerplate code and allows for a clear separation of database queries and application logic.

Transaction functions are also desirable since they encapsulate retry logic and allow for the greatest degree of flexibility when swapping out a single instance of server for a cluster.

Transaction functions can be called as either read or write operations. This choice will route the transaction to an appropriate server within a clustered environment. If you are operating in a single instance environment, this routing has no impact. It does give you flexibility if you choose to adopt a clustered environment later on.

Before writing a transaction function *it is important to ensure that it is designed to be idempotent*. This is because a function may be executed multiple times if initial runs fail.

Any query results obtained within a transaction function should be consumed within that function, as connection-bound resources cannot be managed correctly when out of scope. To that end, transaction functions can return values but these should be derived values rather than raw results.

Transaction functions are the recommended form for containing transactional units of work.

When a transaction fails, the driver retry logic is invoked. For several failure cases, the transaction can be immediately retried against a different server. These cases include connection issues, server role changes (e.g. leadership elections) and transient errors.

The methods `ExecuteRead` and `ExecuteWrite` have replaced `ReadTransaction` and `WriteTransaction`, which are deprecated in version 5.x and will be removed in version 6.0.

```
Unresolved directive in session-api.adoc - include::/opt/teamcity-agent/work/617a3392e5115979/neo-technology/mma/go-manual/build/5/mono/modules/api/neo4j/test-integration/examples_test.go[tags=transaction-function]
```

Auto-commit transactions

An auto-commit transaction, or implicit transaction, is a basic but limited form of transaction. Such a transaction consists of only one Cypher query and is not automatically retried on failure. Therefore, any error scenarios will need to be handled by the client application itself.

Auto-commit transactions serve the following purposes:

- simple use cases such as when learning Cypher or writing one-off scripts.
- operations such as batched data load operations, where the driver cannot be aware of the committed state and therefore cannot safely request a retry. The operator will have to perform a `retry` or `undo` under these circumstances.

The driver does not retry auto-commit queries on failure since it is unaware of what state has been committed at the point of failure.

Unlike other kinds of Cypher query, `CALL {} IN TRANSACTIONS` queries do not participate in the causal chain. Therefore, the only way to execute these queries from a driver is to use auto-commit transactions.

Please refer to the following for more details:

- [Cypher Manual](#) → `CALL {} IN TRANSACTIONS`

```
Unresolved directive in session-api.adoc - include::/opt/teamcity-agent/work/617a3392e5115979/neo-technology/mma/go-manual/build/5/mono/modules/api/neo4j/test-integration/examples_test.go[tags=autocommit-transaction]
```

Consuming results

Query results are typically consumed as a stream of records. The drivers provide a way to iterate through that stream.

```
Unresolved directive in session-api.adoc - include::/opt/teamcity-agent/work/617a3392e5115979/neo-technology/mma/go-manual/build/5/mono/modules/api/neo4j/test-integration/examples_test.go[tags=result-consume]
```

Retaining results

Within a session, **only one result stream can be active at any one time**. Therefore, if the result of one query is not fully consumed before another query is executed, the remainder of the first result will be automatically buffered within the result object.

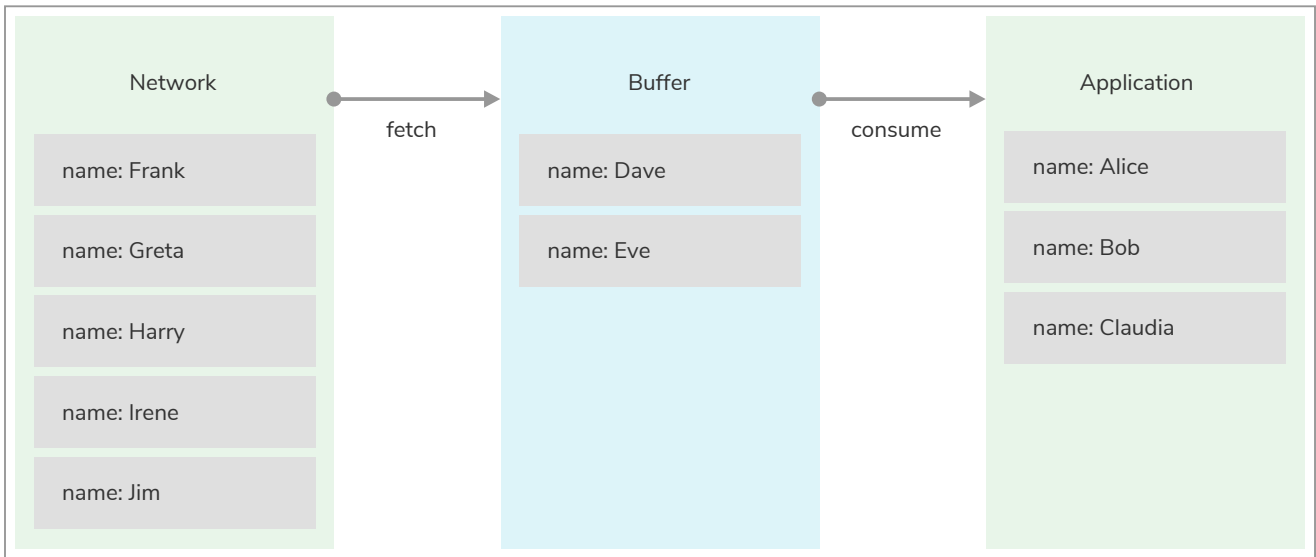

Figure 6. Result buffer

This buffer provides a staging point for results, and divides result handling into **fetching** (moving from the network to the buffer) and **consuming** (moving from the buffer to the application).

For large results, the result buffer may require a significant amount of memory.

For this reason, *it is recommended to consume results in order wherever possible.*

Client applications can choose to take control of more advanced query patterns by explicitly retaining results. Such explicit retention may also be useful when a result needs to be saved for future processing. The drivers offer support for this process, as per the example below:

```
Unresolved directive in session-api.adoc - include::/opt/teamcity-agent/work/617a3392e5115979/neo-technology/mma/go-manual/build/5/mono/modules/api/neo4j/test-integration/examples_test.go[tags=result-retain]
```

Session configuration

Bookmarks

The mechanism which ensures causal consistency between transactions within a session. Bookmarks are implicitly passed between transactions within a single session to meet the causal consistency requirements. There may be scenarios where you might want to use the bookmark from one session in a different new session.

Default: None (Sessions will initially be created without a bookmark)

Default Access Mode

A fallback for the access mode setting when transaction functions are not used. Typically, access mode is set per transaction by calling the appropriate transaction function method. In other cases, this setting is inherited. Note that transaction functions will ignore/override this setting.

Default: Write

Database

The database with which the session will interact. When working with a database which is not the default (i.e. the `system` database or another database in Neo4j 4.0 Enterprise Edition), you can explicitly configure the database which the driver is executing transactions against.

The resolution of database aliases occurs at connection creation time, which is not under the control of the session. It is therefore not recommended to alter database aliases while there are live sessions. The per-user home database is resolved at session creation and when first impersonating a user. Therefore, the creation of a new session is necessary to reflect a changed home database.

See [Operations Manual → The default database](#) for more information on databases.

See below and [Cypher Manual → The DBMS IMPERSONATE privileges](#) for more information on impersonation.

Default: the default database as configured on the server.

See more about [Database selection](#).

Fetch Size

The number of records to fetch in each batch from the server. Neo4j 4.0 introduces the ability to pull records in batches, allowing the client application to take control of data population and apply back pressure to the server.

Default: 1000 records

Impersonated User

Users can run transactions against the database as different users if they have been granted explicit permission for doing so. When impersonating a user, the query is run within the complete security context of the impersonated user and not the authenticated user (i.e., home database, permissions, etc.).

See [Operations Manual → Per-user home databases](#) for more information on default database per-user.

Default: None (Sessions will be created with the logged user)

Transaction configuration

Additional configuration can be provided to transaction which are executed.

Transaction timeout

A timeout value can be provided and transactions which take longer than this value to execute on the server will be terminated. This value will override the value set by `dbms.transaction.timeout`. If no value is provided, the default is taken by the server setting (see [Operations Manual → Transaction Management](#)).

Note: Using with Neo4j 4.1 and earlier it is possible for the driver to override any value set with `dbms.transaction.timeout`. In 4.2 and later, `dbms.transaction.timeout` also acts as a maximum which the driver cannot override. For example, with a server setting of `dbms.transaction.timeout=10s` the driver can specify a shorter timeout (e.g. 5 seconds) but not a value greater than 10 seconds. If a greater value is supplied the transaction will still timeout after 10 seconds.

Default: Configured on server with `dbms.transaction.timeout`.

```
Unresolved directive in session-api.adoc - include::/opt/teamcity-agent/work/617a3392e5115979/neo-technology/mma/go-manual/build/5/mono/modules/api/neo4j/test-integration/examples_test.go[tags=transaction-timeout-config]
```

Metadata

Transactions can be tagged with metadata which will be attached to the executing transaction and visible in various output when listing transactions and queries as well as appearing in the query log.

Default: None.

```
Unresolved directive in session-api.adoc - include::/opt/teamcity-agent/work/617a3392e5115979/neo-technology/mma/go-manual/build/5/mono/modules/api/neo4j/test-integration/examples_test.go[tags=transaction-metadata-config]
```

Appendix A: Driver terminology

This section lists the relevant terminology related to Neo4j drivers.

access mode

The mode in which a transaction is executed, either read or write.

acquire (connection)

To borrow a driver connection that is not currently in use from a connection pool.

auto-commit

A single query which is wrapped in a transaction and committed automatically.

Bolt

Bolt is a Neo4j proprietary, binary protocol used for communication between client applications and database servers. Bolt is versioned independently from the database and the drivers.

Bolt Routing Protocol

The steps required for a driver to obtain a routing table from a cluster member.

Bolt server

A Neo4j instance that can accept incoming Bolt connections.

bookmark

A marker for a point in the transactional history of Neo4j.

causal chaining

A mechanism to ensure that the transactions carried out in a session are executed in order, even when each transaction may be carried out on different cluster members.

client application

A piece of software that interacts with a database server via a driver.

connection

A persistent communication channel between a client application and a database server.

connection pool

A set of connections maintained for quick access, that can be acquired and released as required.

driver (object)

A globally accessible controller for all database access.

driver (package)

A software library that provides access to Neo4j from a particular programming language. The Neo4j drivers implement the [Bolt](#) protocol.

query result

The stream of records that are returned on execution of a query.

release (connection)

To return a connection back into a connection pool after use.

routing driver

A driver that can route traffic to multiple members of a cluster using the routing protocol.

routing table

A set of server addresses that identify cluster members associated with roles.

server address

A combination of host name and port or IP address and port that targets a server.

session

A causally linked sequence of transactions.

thread safety

See https://en.wikipedia.org/wiki/Thread_safety.

transaction

A transaction comprises a unit of work performed against a database. It is treated in a coherent and reliable way, independent of other transactions. A transaction, by definition, must be atomic, consistent, isolated, and durable.

transaction function

The method of grouping a number of queries together which, when run in a session, are retried on failure.

transaction manager

The component/code responsible for deciding what to do if a transaction fails, i.e to retry, give up or do something else.
